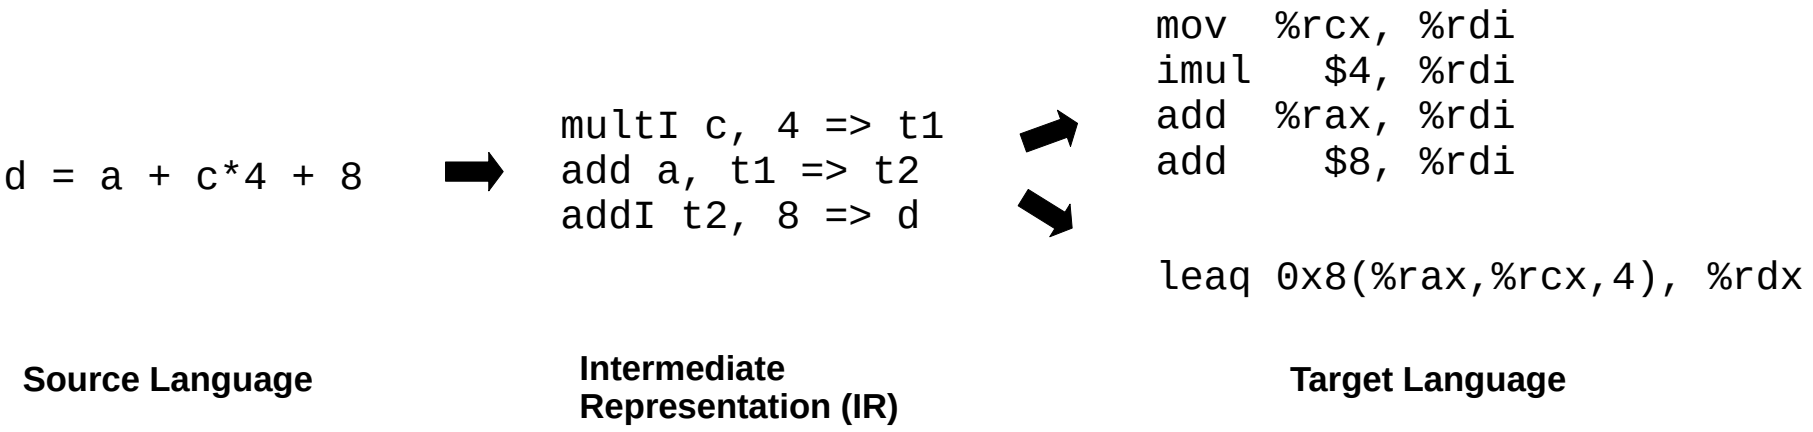
Machine Code Gen (Ch. 11-13)

- Translate from (usually linear) IR to machine code
  - Often, compilers will just emit assembly
  - Use built-in system assembler and linker to create final executable

- Issues:
  - Translation from IR instructions to machine code instructions
    - **Instruction selection** ***(Ch. 11)*** *- example in* `y86.c` *provided w/ P5*
  - Arrangement of machine code instructions for optimal pipelining
    - **Instruction scheduling** ***(Ch. 12)*** *- algorithm next week; no implementation*
  - Assignment of registers to minimize memory accesses
    - **Register allocation** ***(Ch. 13)*** *- primary focus of P5*

Instruction Selection

- Choose machine code instructions to replace IR
  - Complexity is highly dependent on target architecture
  - CISC provides more options than RISC (e.g., x86 vs. ARM)
    - Tradeoff: *(possible)* performance improvement vs. compiler complexity
- Algorithms:
  - Treewalk routine (similar to P4)
  - Tree-pattern matching / tiling (variant implemented in `y86.c` in P5)



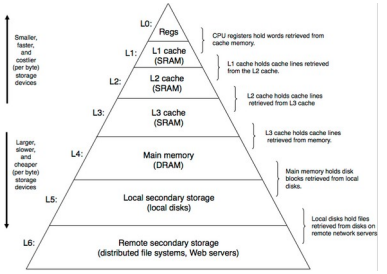
Instruction Scheduling

- Modern CPUs expose many opportunities for optimization
  - Some instructions require fewer cycles
  - Instruction pipelining
  - Branch prediction and speculative execution
  - Multicore shared-memory processors

- Scheduling: re-order instructions to improve speed
  - Must not modify program semantics
  - Maximize utilization of CPU and memory resources
  - Main algorithm: **list scheduling** (next week!)

Register Allocation

- Maximizing register use is very important
  - Registers are the lowest-latency memory locations
  - Issue: limited number of registers
    - Everything not in registers must be stored in cache or main memory
  - Need to reduce the # of registers used to match the target system
  - Program using *n* registers => Program using *m* registers (*n* >> *m*)



Credit: CS:APP

- Allocation vs. assignment
  - Allocation: map a virtual register space to a physical register space
    - This is hard (NP-complete for any realistic situation)
  - Assignment: map a valid allocation to actual register names
    - This is easy (linear or polynomial)

Question

- Which virtual registers should be allocated to “real” physical registers and which must be allocated elsewhere?

```
add:
  loadAI [bp+16] => r0
  loadAI [bp+24] => r1
  add r0, r1 => r2
  i2i r2 => ret
  return

main:
  loadI 3 => r3
  storeAI r3 => [bp-8]
  loadAI [bp-8] => r4
  loadI 2 => r5
  param r5
  param r4
  call add
  i2i ret => r6
  i2i r6 => ret
  return
```

Local Allocation

- Top-down local register allocation
  - Compute a priority for each virtual register
    - Frequency of access to that register
  - Sort by priority, highest to lowest
  - Assign registers in order, highest priority first
  - Rewrite the code

- General idea: prioritize most-often-accessed virtual registers
  - Allocate to physical registers in priority order
  - Very simple to implement
  - Static per-block allocations are not always optimal
    - Access patterns may change throughout block
    - Especially in SSA form where registers aren’t often re-used

Local Allocation

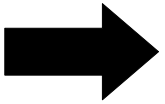
- Bottom-up local register allocation
  - Scan each block instruction-by-instruction
    - Essentially, simulate running the program
  - Maintain physical-to-virtual register mapping (“Name”)
    - Initialize registers to empty (“INVALID”) at beginning of block
  - For each instruction:
    - Assign virtual registers to physical registers
    - Ensure operands are in physical registers (load them if not)
    - Greedy algorithm: choose best allocation available at each instruction
      - Track next reference and free physical registers as soon as possible

Example

Suppose we have three physical registers:

Name[R0] ~~= INVALID~~ ~~r0~~ ~~INVALID~~ ~~r2~~ INVALID
Name[R1] ~~= INVALID~~ ~~r1~~ INVALID
Name[R2] = INVALID

```
add:
  loadAI [bp+16] => r0
  loadAI [bp+24] => r1
  add r0, r1 => r2
  i2i r2 => ret
  return
```

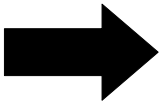


```
add:
  loadAI [bp+16] => R0
  loadAI [bp+24] => R1
  add R0, R1 => R0
  i2i R0 => ret
  return
```

Example

```
add:
  loadAI [bp+16] => r0
  loadAI [bp+24] => r1
  add r0, r1 => r2
  i2i r2 => ret
  return

main:
  loadI 3 => r3
  storeAI r3 => [bp-8]
  loadAI [bp-8] => r4
  loadI 2 => r5
  param r5
  param r4
  call add
  i2i ret => r6
  i2i r6 => ret
  return
```



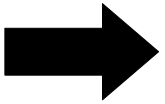
```
add:
  loadAI [bp+16] => R0
  loadAI [bp+24] => R1
  add R0, R1 => R0
  i2i R0 => ret
  return

main:
  loadI 3 => R0
  storeAI R0 => [bp-8]
  loadAI [bp-8] => R0
  loadI 2 => R1
  param R1
  param R0
  call add
  i2i ret => R0
  i2i R0 => ret
  return
```

Only needed **two** physical registers for this example!

Example

```
gcd:
l1:
  loadAI [bp+24] => r0
  loadI 1 => r1
  cmp_GE r0, r1 => r2
  cbr r2 => l2, l3
l2:
  loadAI [bp+24] => r3
  loadI 0 => r4
  store r3 => [r4]
  loadAI [bp+16] => r5
  loadAI [bp+24] => r6
  div r5, r6 => r7
  mult r6, r7 => r8
  sub r5, r8 => r9
  storeAI r9 => [bp+24]
  loadI 0 => r10
  load [r10] => r11
  storeAI r11 => [bp+16]
  jump l1
l3:
  loadAI [bp+16] => r12
  i2i r12 => ret
  return
```



```
gcd:
l1:
  loadAI [bp+24] => R0
  loadI 1 => R1
  cmp_GE R0, R1 => R0
  cbr R0 => l2, l3
l2:
  loadAI [bp+24] => R0
  loadI 0 => R1
  store R0 => [R1]
  loadAI [bp+16] => R0
  loadAI [bp+24] => R1
  div R0, R1 => R2
  mult R1, R2 => R1
  sub R0, R1 => R0
  storeAI R0 => [bp+24]
  loadI 0 => R0
  load [R0] => R0
  storeAI R0 => [bp+16]
  jump l1
l3:
  loadAI [bp+16] => R0
  i2i R0 => ret
  return
```

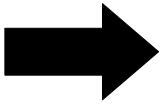
What if we only had two physical registers?

Spilling

- If no physical registers are free, spill one!
  - Store its value to memory and re-load it later
  - For optimal results, spill register that will be accessed the furthest in the future
    - Store Next[pr] for this purpose or just re-calculate when needed
- This is the hardest part of P5 (leave it for last!)
  - Allocate slot in stack frame for each spilled register
    - It’s essentially a new local variable
  - Track the offset for each virtual register
  - Emit load/store instructions as needed
    - **Significant helper code is provided!**

Bottom-up local register allocation

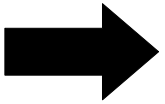
```
gcd:
l1:
  loadAI [bp+24] => r0
  loadI 1 => r1
  cmp_GE r0, r1 => r2
  cbr r2 => l2, l3
l2:
  loadAI [bp+24] => r3
  loadI 0 => r4
  store r3 => [r4]
  loadAI [bp+16] => r5
  loadAI [bp+24] => r6
  div r5, r6 => r7
  mult r6, r7 => r8
  sub r5, r8 => r9
  storeAI r9 => [bp+24]
  loadI 0 => r10
  load [r10] => r11
  storeAI r11 => [bp+16]
  jump l1
l3:
  loadAI [bp+16] => r12
  i2i r12 => ret
  return
```



```
gcd:
l1:
  loadAI [bp+24] => R0
  loadI 1 => R1
  cmp_GE R0, R1 => R0
  cbr R0 => l2, l3
l2:
  loadAI [bp+24] => R0
  loadI 0 => R1
  store R0 => [R1]
  loadAI [bp+16] => R0
  loadAI [bp+24] => R1
  div R0, R1 => ???
  mult R1, ??? => R1
  sub R0, R1 => R0
  storeAI R0 => [bp+24]
  loadI 0 => R0
  load [R0] => R0
  storeAI R0 => [bp+16]
  jump l1
l3:
  loadAI [bp+16] => R0
  i2i R0 => ret
  return
```

Bottom-up local register allocation

```
gcd:
l1:
  loadAI [bp+24] => r0
  loadI 1 => r1
  cmp_GE r0, r1 => r2
  cbr r2 => l2, l3
l2:
  loadAI [bp+24] => r3
  loadI 0 => r4
  store r3 => [r4]
  loadAI [bp+16] => r5
  loadAI [bp+24] => r6
  div r5, r6 => r7
  mult r6, r7 => r8
  sub r5, r8 => r9
  storeAI r9 => [bp+24]
  loadI 0 => r10
  load [r10] => r11
  storeAI r11 => [bp+16]
  jump l1
l3:
  loadAI [bp+16] => r12
  i2i r12 => ret
  return
```



```
gcd:
l1:
  loadAI [bp+24] => R0
  loadI 1 => R1
  cmp_GE R0, R1 => R0
  cbr R0 => l2, l3
l2:
  loadAI [bp+24] => R0
  loadI 0 => R1
  store R0 => [R1]
  loadAI [bp+16] => R0
  loadAI [bp+24] => R1
  storeAI R0 => [bp-8]  // store r5
  div R0, R1 => R0
  mult R1, R0 => R1
  loadAI [bp-8] => R0   // load r5
  sub R0, R1 => R0
  storeAI R0 => [bp+24]
  loadI 0 => R0
  load [R0] => R0
  storeAI R0 => [bp+16]
  jump l1
l3:
  loadAI [bp+16] => R0
  i2i R0 => ret
  return
```

Full algorithm

for each instruction *i* in program:

    for each *vr* read in *i*:
        pr = **Ensure**(vr)
        replace *vr* with *pr* in *i*
        if *vr* is not needed after *i* then free *pr*

    for each vr written in i:
        pr = **Allocate**(*vr*)
        replace *vr* with *pr* in *i*

Ensure(vr):
    if *vr* is in *pr*:
        return *pr*
    else:
        pr = **Allocate**(*vr*)
        emit load from *vr*
        return *pr*

Allocate(vr):
    if *pr* is available:
        return *pr*
    else:
        find furthest-used *pr* to spill
        emit spill for *pr*
        return *pr*

Textbook vs. reference compiler

- Textbook algorithm uses a stack to store free registers
  - Must remember to add registers to stack when freeing them
  - O(1) access to a free register if one is available
- Reference compiler scans physical registers for first free one
  - O(*k*) where *k* is number of physical registers, which is essentially a small constant
  - Only need Name[*pr*]
    - *pr* is free if Name[*pr*] == INVALID

TEXTBOOK:

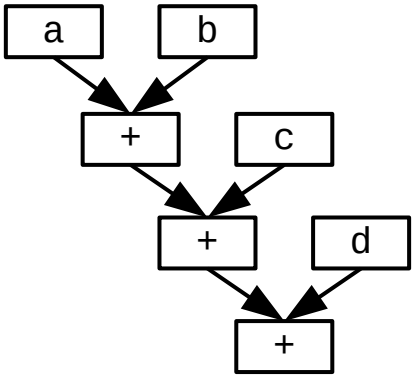
```
loadI 1 => R0
loadI 2 => R1
add R0, R1 => R1
```

REFERENCE:

```
loadI 1 => R0
loadI 2 => R1
add R0, R1 => R0
```

Expression evaluation

- How many registers does it take to evaluate an arbitrary expression without any spilling?
  - Is there an easy way to determine this?

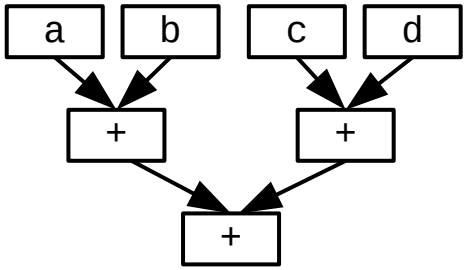


For example:

a + b + c + d

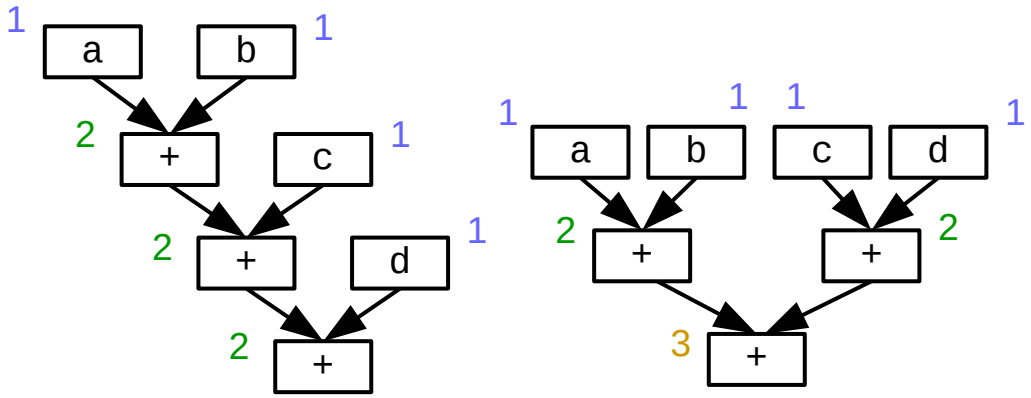
vs.

(a+b) + (c+d)



Expression evaluation

- How many registers does it take to evaluate an an arbitrary expression without any spilling?
  - Examine the expression tree (e.g., parse tree)
  - Calculate the Strahler number:
    - If the node is a leaf (has no children), its Strahler number is one.
    - If the node has one child with Strahler number i, and all other children have Strahler numbers less than i, then the Strahler number of the node is i.
    - If the node has two or more children with Strahler number i, and no children with greater number, then the Strahler number of the node is i + 1.



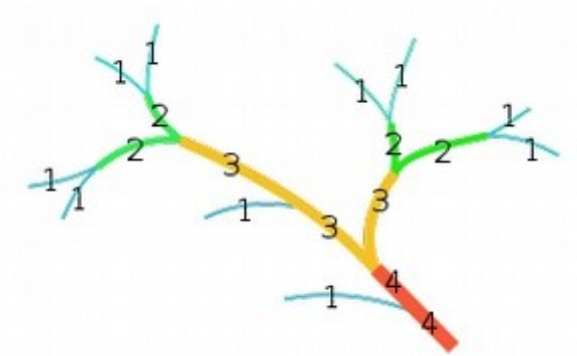


Image from https://en.wikipedia.org/wiki/Strahler_number

Systems design tradeoff

- Parallelism vs. register pressure
  - Balanced trees provide more parallelism and (as we'll see next week) better pipelining
    - However, more spills => worse performance
  - Unbalanced trees require fewer registers
    - Fewer spills => better performance
    - However, fewer opportunities for parallelism and pipelining
  - Usually the parallelism is worth the increased register pressure
    - Especially in the presence of forwarding and robust caches

Local vs. global allocation

- Local allocation handles each basic block separately
  - Will miss inter-block dependencies
- Global allocation handles all basic blocks in a procedure
  - Does NOT consider inter-procedural dependencies
  - This is why calling conventions are important
    - I.e., caller-save vs. callee-save and return value
- Decaf project
  - Because we used SSA in P4 and always load/store to memory, no virtual registers will be live at the entrance or exit of any block (so no inter-block dependencies)
  - Thus, we can use local register allocation in P5

Global Allocation

- Discover global live ranges of related uses and definitions
  - For each use, any reaching definitions must be in the same range
  - For each definition, any reachable uses must be in the same range
  - Simple disjoint-set union-find algorithm over SSA form
- Build interference graph
  - Node for each live range and edges between interfering live ranges
- Attempt to compute graph *k*-coloring
  - *k* is the number of physical registers
  - Greedy algorithm: order the colors (registers)
    - For each vertex, choose smallest color not shared by neighbors
  - If successful, done!
  - If not successful, spill some values and try again
    - Need a robust way to pick which values to spill
    - Alternatively, split live ranges at carefully-chosen points

Towards Inductive Synthesis of Compiler Heuristics: A Case Study with Register Allocation

Mohammad Ali
Texas State University

apan@txstate.edu

Motivation

- There have been significant advances in machine learning-driven performance modeling in recent years.
- One key limitation of such approaches is that their success depends, to a large degree, on the formulation of the outcome or objective, which is typically done by human experts
- In this work, we propose a new approach to automatically generating compiler optimization heuristics using inductive program synthesis

Given a program representation and a specification of an optimization task as input, generate an algorithm for that optimization that maximizes performance

Graph-Coloring Register Allocation

- Compilers apply a host of code transformations that require solving data-flow analysis problems that are intractable.
- In this poster, we investigate graph-coloring register allocation, an NP-hard problem
- Graph-coloring register allocators today apply a complex set of heuristics for live range splitting and coalescing, eviction, spilling, and coloring, which can all be formulated as transformations on the SSA, Live Range, and Interference graphs

We define the synthesis of a live range (LR) splitting algorithm as follows

Given a set of input-output samples, generate a program that transforms an input LR graph through a sequence of split operations, to produce an output LR graph, which is most likely to minimize spill cost

Methodology

Our framework for inductive synthesis for register allocators includes the following components

- Compiler Graph Generator (CGG): generates arbitrary SSA graphs with embedded Live Ranges (LR)
- Graph Transformation Language (GTL): a language to express graph transformations for register allocation
- Graph Program Generator (GPG): generates arbitrary legal programs written in GTL
- Interpreter: given an input graph generated by CGG and a program generated by GTL, applies the program to the input graph and produces the resulting output graph

For inductive program synthesis, we employ a Genetic Algorithm (GA)

- A GTL program is an individual with a single chromosome and a split is a gene
- Cross-over, mutation, and roulette selection are applied to genomes which consist of a sequence of split operations
- The fitness score is calculated as a function of the number of LRs and the length of each LR Intuitively, a chromosome with a higher fitness score is likely to result in fewer spills.

Experimental Results

Conclusions and Future Work

- This work provides initial evidence that inductive synthesis can be an effective tool for creating new heuristics for complex code optimizations
- The structure of the live range graph can have a significant impact on convergence time
- Future work includes extending the framework to include the full suite of RA transformations including eviction and coloring, replacing GA with more sophisticated techniques such as the Multi-Armed Bandit, and applying the approach to value numbering and instruction scheduling tasks
